MARIPOSA Vol. II, # 1 Editor: H.P.McDonald Publ. Quarterly Editorial Address: 260 Alden Rd. Hayward, Ca. 94541

The Calochortus Society
Newsletter
July 1990
Advisors: C. Baccus, S.
Farvig, V. Girard,
and B. Ness

I. ANNOUNCEMENTS:

1. Starting with this issue we are slightly altering the format of the newsletter. The detailed examination of a single sp. will be in the back of the newsletter, and other items have been moved forward. Also, Georgie Robinette has kindly consented to computerize our mailing list.

2. Dr. Peggy Fiedler has been picked to treat Calochortus for the Flora

2. Dr. Peggy Fiedler has been picked to treat Calochortus for the Flora of North America project by the Missouri Botanical Garden. Dr. Fiedler, who did her Doctoral dissertation on Calochorti at UCBerkeley, is with

the Biology Dep't at Cal. St. Univ. San Francisco.

3. C. monanthus update. A Cal. Nat. Plant Soc. representive, Dr. Mark Skinner, was among the visitors to a site in No. California where it was rumored that C. monanthus (see Mariposa #2), thought to be extinct, might be growing. Although none was found, the survey team was on the early side for the historic date of this species. Further, it has been a dry year in the region, and C. monanthus may not have bloomed.

4. For new subscribers (and some renewals), here is a list of the best

sources for Calochortus:

A. Bulbs: C. Baccus 900 Boynton Ave. San Jose, Ca. 95117 Offers 10-20 spp./yr. Chuck invites inquiries on spp. which are not listed on the order form, but which he may have in small quantities. Mostly Cal. spp.

--Robinette Bulb Farm P.O.Box 1306 Sebastipol, Ca. 95473-1306 Three spp. this year in the form of bulbs, but many more

in seed form, esp. no. Cal. spp.

B. Seeds: Theo. Payne Foundation 10459 Tuxford St. Sun Valley, Ca.
91352. Good source for S. Cal. spp. List changes annually.
--Southwestern Native Seed Box 50503 Tucson, Az. 85703. Tim
and Sally Walker's seed list is incredible. They are the
only source I know of for the Mexican spp., and also offer
Rocky Mt. and Northwest spp.

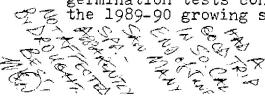

5. I am offering a small quantity of seed of some rarer spp. free to members. As some members live in cold areas where it is difficult to grow the lowland California types, I am offering two spp. One is the lovely C. nitidus, seeds courtesy of Prof. Watson. This sp. is suitable for cold climates, as it tolerates at least -20°F in its native range. It also gets summer water. For warmer climates, I will offer C. clavatus, from coastal Cal. As my supply is limited, please request only one sp. Send a stamped, self-addressed envelope to ACS.

6. Rob Charnock, a member from Springwood, Australia is interested in contacting other growers to trade/buy seed. Mr. Charnock has Australian terrestrial orchids and Vireya Rhododendrons, among others, as well as the requisite permits. Interested members can write to Mr. Charnock at #3.

Stanway Ave. Springwood, NSW 2777 Australia. II. Mixes: Jim Robinette's Mix-

50% fine fir bark, 10% coarse sand, 10% lava rock ($\frac{1}{4}$ "), 10% perlite, 10% vermiculite, 10% peat moss. Add slightly more peat moss for section Calochortus (the pussy ears, fairy lanterns, etc.), and slightly less perlite. For section Mariposa, reverse this: more perlite, less peat. For the desert types add slightly more sand.

Despite the higher rainfall totals in their area, as compared with Hayward, San Jose, and Concord, the Robinettes have been successful with many varieties of Calochorti, to speak nothing of lilies, frittillarias, etc. III. Calochortus Germination Tests: First Installment—Seed Planting Depth This is the first in a series which will give the results of various germination tests conducted at two locales in Alameda Co., Cal. during the 1989-90 growing season. Readers are cautioned that many of these re-

sults are preliminary, and that more time and study are needed if more conclusive results are to be established. Our thanks to Mr. Ron Liljedahl, who directs the horticulture program at Chabot College in Livermore, Ca., for his invaluable assistance, and the use of space at the College in which to conduct the tests. Our thanks also to our advisors, Mr. C. Baccus, Mr. S. Farwig, Mr. V. Girard; also to Mr. and Mrs. J. Robinette, and Dr. P. Fiedler.

To determine optimum planting depth, we tested six spp. from all three divisions: C. albus, C. Tolmiei, C. uniflorus; C. catalinae, C. venustus; and C. weedii. (These spp. were chosen because their ranges are relatively large, because they occupy distinctive habitats and climatic zones, and because all have been raised successfully as garden subjects by one or another grower.) Every effort was made to keep other variables, e.g., water, temperature, etc. constant, so as to accurately test one variable only, in this case the optimum planting depth for seed of Calochortus. Each sp. was planted in pots, with identical, sterilized media, at varying depths, viz., surface, 1" $\frac{1}{2}$ ", 1", and 2" deep. The mix, modified from a successful media developed by Mr. C. Baccus, consisted in 2/3 humus (bark, 1/8 redwood compost, 1/8 "orchid mix," mostly fine bark, $\frac{1}{4}$ potting mix, which includes sand, and $rac{1}{4}$ mixed grade sand. The total sand in the mix was approximately 1/3). This mix was used because it has a good track record, and combined drainage with water retention. The pots were watered twice a week until germination, and then once a week. As no known rules for watering could be drawn upon, we took the average annual precipitation during the growing season in their indigenous ranges for the spp. tested as our guide. This is higher than average for the southern spp. and lower than average for the northern. While this could skew the results, it seemed better to opt for a uniform watering schedule, especially as the use of pots is already a move away from indigenous conditions.

Horticulturalists use a rule of thumb for spp. whose optimum planting depth is unknown. It is to plant seed "2-3 times the smallest overall diameter" deep. While section Mariposa seeds are large on their flat face, about 3x4 mm, they are no larger in their "smallest overall diameter" than seeds of the other sections. In general, seeds of the genus Calochortus are about 1 mm in their "smallest overall diameter," and thus should be planted fairly shallowly, just under the surface.

The results of the test were that, for all spp.*, the $\frac{1}{4}$ " depth proved superior (*except for C. weedii, none of whose seed germinated in any of the tests. These tests will be repeated this fall for C. weedii from another seed source). All spp.* emerged at this planting depth, and did so well before some of the others. Interestingly, this held for small seed (sect. Calochortus) as much as for larger seed. Surface sown seeds germinated much later than those planted at $\frac{1}{4}$ ", in one case considerably so (2 mos.--C. albus). In two cases, surface sown seed failed to germinate (C. Tolmiei, C. Venustus). The late germination was consistent for the surface sown spp. which did germinate.

The $\frac{1}{2}$ " depth proved to be second best. Four of six spp. germinated at this depth, and three of these did so at roughly the same time as those planted at $\frac{1}{4}$ " (C. uniflorus and C. weedii did not germinate; C. Tolmiei germinated later at $\frac{1}{2}$ " than at $\frac{1}{4}$ " by $1\frac{1}{2}$ mos.). Only one sp., C. venustus, germinated at 1"; and only one at 2" (C. uniflorus).

This test is, at best, only tentative. A comprehensive test would require testing of all 6 spp. x 8 media x at least 4 watering schedules x the 5 depths=960 pots and about 15,000 seed (15/pot). This is well beyond the resources available to us (we did conduct media and watering tests separately, among others. These will be released in future volumes). Further, the tests are interrelated. It is difficult to conduct a planting depth test without knowing the optimum media and water schedule, and vice versa. Thus continued testing is required.

Nevertheless, it would seem that too deep or too shallow planting is ill-advised. The earlier germination of the seed planted at $\frac{1}{2}$ ", and to a lesser degree at $\frac{1}{2}$ ", may be vital for the success of the plant. Germination at too late a date may allow for insufficient time to grow and to form a tiny bulb, which can live over through the dormant period. This consideration may be more important in the wild, but it is not without application to Calcebortus horticulture.

IV. The Horticultural History of Calochortus—4th Installment.

MacSelf, A.J., Bulb Gardening, N.Y.: Chas. Scribner's Sons, 1925. 1st

ed. publ. in Unit. King.

"This genus richly deserves to occupy front rank among the choicest of bulbs for unheated greenhouses... In favored Southern (British) gardens Calochortus will succeed quite well out of doors, but in windy or otherwise unfavourable localities it is a pity to allow the beauty of the flowers to be marred by bad weather if any covering of glass is available to keep them clean and unbruised...

"...Unlike the rest of the tribe these smaller kinds which produce drooping globular blossoms prefer shade, or at any rate partial shade, but

the other sections cannot have too much sun...

"Three good bulbs in a 5-inch pot will make a good show. A light, sandy loam, some peat and leaf-mould in equal proportions and a good addition of silver sand will make a suitable compost. Pots should be very well-drained, and the bulbs should be potted in October, started in a frame, removed to a sunny position (except the Globe varieties) as soon as growth appears, and thenceforward be kept liberally watered until flowering has finished, when they should be thoroughly ripened and well roasted in the sun. In October shake out, separate the offsets, which should be grown on in pans, and repot the large bulbs as before. Feeding with liquid manure during growth is permissible but must be done with cautious moderation."

This selection, which brings us into the twenties, again reflects British experience in growing Calochorti (cf. Mariposa I,4). Only California spp. are mentioned in the rest of the text (edited out; Carl Purdy as the source of the bulbs?). Yet the best spp. for cold climates like that of the Un. Kingdom are mostly from outside California. The author seems almost to be quoting the Sanders selection (Mariposa I,4) in part of his treatment: the first such derivative approach of many that I have come across. "Ripened" means, presumably, dried out during dormancy. A five inch pot is too small for section Mariposa. The use of an unheated greenhouse may be suitable for cold climates, but not warm ones: the bulbs require some chilling (with a few exceptions) to do well. The soil mix sounds reasonably good if inexact.

V. Conservation: the California Native Plant Society Inventory

The Cal. Native Plant Society has for several years published an Inventory of Rare and Endangered Vascular Plants of California. This volume has provided a valuable source for information on the shrinking ranges of many native Cal. spp., the many threats to their survival from development, ground water pumping, grazing, etc., and a ranking system which separates various categories of endangerment, from possible threats to immediate.

The 1988 ed. of the Inventory lists 23 spp. or varieties of Calochor-

The 1988 ed. of the <u>Inventory</u> lists 23 spp. or varieties of <u>Calochortus</u>. Of these, I is presumed extinct, 2 are considered to have taxonomic validity problems, 2 are considered but rejected as "too common." Of the remaining 18, three are listed by the State of California as rare and endangered. An additional eight are considered rare and endangered by the CNPS, but, for various reasons, have not yet been listed by the State. The other seven are on the "watch list." This last contains plants which are not yet rare or endangered, but could become so given present trends.

The CNPS should be applauded for its work in collecting information on these plants, for its publishing and publicizing threats to various spp., and for its efforts at conservation. No other organization has come close

to the CNPS at documenting the assault on California Flora, and to its attempt to halt and reverse the decline of the native biosphere. As far as it goes, the Calochorti listing in the Inventory is well-considered. Nevertheless, the list is incomplete. There are many spp. and var. of Calochortus which are not in the Inventory which are either intrinsically rare or have become so due to human encroachment.

A species is intrinsically rare if its original (known) range is confined to one or a few small areas. For example, C. panamintensis (C. Nuttallii var. panamintensis) is confined to two small stands in the Panamint Mts. of SE California. This is a confined habitat indeed: one area of one county of one state. By contrast, the range of <u>C. nuttallii</u> var. <u>nuttallii</u>, the species proper, extends across parts of ten or more states. <u>C. panamin</u>tensis is not listed in the Inventory. Other spp. or varieties which are intrinsically rare but not listed are <u>C. clavatus</u> var. <u>gracilis</u>, <u>C. weedii</u> var. <u>intermedius</u>, <u>C. coeruleus</u> var. <u>fimbriatus</u>, and <u>C. elegans</u> var. <u>nanus</u>.

Two others are rare due to the extensive expansion of human settlements into their original range. C. plummerae was listed as "common" 100 years ago (Parrish), but is now quite reduced. Unfortunately, its habitat lies in areas attractive to Los Angeles developers. Perhaps two-thirds of its known stands have been eliminated for housing. A similar fate has befallen the enchanting variety of \underline{C} . weedii, var. \underline{vestus} in Santa Barbara and Ventura Counties. While this $\underline{variety}$, which some consider a separate sp., was never common, it is now much reduced due to human expansion. VI. Species This Issue: <u>C.@urycarpus</u>
Range: From E oregon through Idaho to W Montana and NW Wyoming. Disjunct

population in NE Nevada.

Botany: C. eurycarpus is the most widespread of the "Nitidi" subsection of section (eu)calochortus. The flowers of this section are upright, as in the "Nudi" subsection, which differentiates them from the fairy lanterns. Unlike most of the nudi, however, the seed capsules of the Nitidi tend to remain upright.

C. eurycarpus, from An Illustrated Flora of the Pacific States, by Leroy Abrams, Ph.D., Stanford Univ. Press. 1923. p. 439.

23. Calochortus eurycarpus S. Wats. Big-pod Mariposa. Fig. 1079.

Culm horing our yearpus S. Wats. Box. King Exp. 345

Colorhorius mitidus correctous Hemicison, Rull Torrey Club 27: 556 1906

Stem even, stiff 25/45 em In; h. 4 miscle 1/1:

flowered, sepals of its lanceolast, long action naic, usually exceeding the petals petals white to lavender, with a conspicuous orbicular indigspec in the middle, 25-45 mm, long sparingly tong-villous around the small round gland, this covered with short yellow hans completely conceahing the narrow scale at the base; filamen's dilated below, 10 mm, long, anthers oblong 6-3 mm. long, capsule elliptic, 20-25 mm. long, broadly winged, abruptly rounded at apex to the short beak.

Open meadows, of the Canadian Zone, Blue Mountains, eastern Oregon, to Montana and northern Nevaria Type Doubley: "East Humbolin Mountains, Nevaria, 2,000 9,540 feet altitude."

The Nitidi have hairier petals than the nude star tulips, but not so hairy as the pussy ears. They tend to be larger than the spp. in the other subsections.

C. eurycarpus differs from the other Nitidi in a variety of characters. Unlike C. longebarbatus, it is not bulbiliferous. (Purdy alone claims it is but there is no herbarium record of a bulbiliferous plant, and I have yet to see any evidence in the field of leaf-axil offsets, as opposed to bulb division.) C. nitidus is tetraploid while C. eurycarpus is diploid, with

a haploid chromosome count of 10. From <u>C. Greenei</u> and <u>C. Howellii</u> it differs in range, color, and in the shape of the gland. Finally, <u>C. persistens</u>, alone of the <u>Nitidi</u>, has nodding seed capsules, while the others, including <u>C. eurycarpus</u>, have upright capsules. (Ownbey classifies <u>C. lyalli</u> as a <u>Nitidi</u>, but is inconsistent in his criteria for doing so. While <u>C. lyallii</u> is difficult to classify, it is far closer to the pussy ears than to the larger Nitidi.)

The botanical literature has differed on whether the sepals of C. eurycarpus are longer than the petals or vice versa. Purdy (1901) and Abrams claim that they are, but Ownbey states that the sepals are "usually much shorter than the petals" (1940). Field observation tends to bear out Ownbey on this point, but the sp. has an extensive enough range that there are undoubtedly individual specimens with longer sepals. The flowers are usually white with a purple blotch in the center of the petal, and yellowish hairs surrounding the gland near the base of the petal. In NE Oregon, where it is numerous, there are lilac and purple flowers as well. Purdy mentions a yellow form at Yellowstone, Wy. Purdy and Abrams describe the gland as round, while Ownbey describes it as "triangular-lunate."

HISTORY: The name of the sp. has undergone bewildering changes, making one wonder what plant various botanists are talking about. Purdy and Ownbey (1940) call the plant <u>C. nitidus</u>. Watson, Abrams and the later Ownbey (Vascular Plants of the Pacific Northwest 1969) call it <u>C. eurycarpus</u>. <u>C. nitidus</u> is another sp., but in some of the literature, the author is actually discussing <u>C. eurycarpus</u> when speaking of <u>C. nitidus</u>. The sp. was first described, apparently, by the well regarded botanist S. Watson (1871), and not D. Douglas, as Ownbey first thought. Beside the confusion with <u>C. nitidus</u>, the sp. has been labelled <u>C. parviflorus</u>, <u>C. umbellatus</u>, and <u>C. euumbellatus</u> by different observers. This plethora of names identifies a sp. which is difficult to confuse with any other in the field.

HORTICULTURE: In the wild, <u>C. eurycarpus</u> grows in high mountain meadows (<u>e.g.</u> 4800' in NE Oregon). I have seen it both in part shade and, more rarely, in full sun, but it tends to grow near low shrubs in the sunny locales, so it probably gets some shade there. It grows among low grasses, which may help to shade the lower portions of the plant, as well as provide mulch and compost. Rainfall varies from 10-30"/yr. Much is in the form of snow, and snowmelt probably triggers seedling germination in the spring. However, this sp. does get summer rains. <u>C. eurycarpus</u> is hardy to -30°F(-34°C) in its wild range, but may be hardier yet in cultivation, with snow cover, or other protection. It blooms late spring to early summer, and probably has a short growing season.

In mild winter or hot summer climates <u>C. eurycarpus</u> would be difficult to grow, as it prefers coold winters and mild summers. It should be suited to the No. and E. U.S., however, as well as similar cold winter climates. It is quite hardy, and tolerates some summer water. Cold climate growers can place the seeds in a one-gallon or larger pot, and set it out in winter with snow on top. They may be able to grow it in the ground as well. Heavy soils should be modified with sand and pine leaf-mold in equal proportions (up to 50%. There are records of its being grown in heavy clay-loam, but in a dry climate-Krukeberg, 1982n). In warmer climates, the seeds should be cold stratified in moist vermiculite for 6-10 weeks and then transplanted. I have had some success in pots with the U.C. mix of ½ sand ½ peat moss, and a small amount of low nitrogen, complete bulb fertilizer. Water once a week--less later in the season. The pots should be kept as dry as possible during dormancy.
